ABSTRACT

Multiresolution signal and image models such as the *hidden Markov tree (HMT)* aim to capture the statistical structures of smooth and singular (textured and edgy) regions. Unfortunately, models based on the orthogonal wavelet transform suffer from shift-variance, making them less accurate and realistic. In this paper, we extend the HMT modeling framework to the *complex wavelet transform*, which features near shift-invariance and improved angular resolution compared to the standard wavelet transform. The model is computationally efficient (featuring linear-time computation and processing algorithms) and applicable to general Bayesian inference problems as a prior density for the data. We develop a simple multiscale maximum likelihood classification scheme based on the complex wavelet HMT that outperforms methods based on real-valued wavelet HMTs. The resulting classifier can be used as a front end in a more sophisticated multiscale segmentation algorithm.

1. INTRODUCTION

Modeling lies at the core of much of statistical image processing, and more realistic models yield improved algorithms for compression, estimation, detection, classification, and so on. The success of wavelets in image processing is due primarily to the compact representation of images provided by the discrete wavelet transform (DWT). This compact representation leads to simple characterization of image structure and results in simple yet effective wavelet-domain image models.

The wavelet transform manifests image structure in the following two key properties [1]:

2Populations: Smooth signal/image regions are represented by small wavelet coefficients, while edges, ridges, and other singularities are represented by large coefficients.

Persistence: Large and small wavelet coefficient values cascade along the branches of the wavelet tree.

Interpreting these properties statistically, 2Populations implies that wavelet coefficients have non-Gaussian marginal statistics, with a large peak at zero (many small coefficients) and heavy tails (a few large coefficients), while Persistence implies that wavelet coefficient values are statistically dependent along the branches of the wavelet tree.

The hidden Markov tree (HMT) [1] captures these statistical properties in a model of the joint probability density function (pdf) $f(\mathbf{w})$ for the wavelet coefficients \mathbf{w} of an image. To capture the 2Populations property, we model each wavelet coefficient w_i with a two-state Gaussian mixture; a controlling hidden state s_i records the magnitude of the coefficient as either S (small) or L (large). To capture the Persistence property, we connect the hidden states across scale (down the wavelet tree) in a Markov-1 chain in such a way that the unbroken progressions L-L-L-L and S-S-S-S are more likely than broken ones such as L-L-S-L and S-S-L-S. These latter two progressions lead to edge blurring and ripple artifacts, respectively.

When employed in a Bayesian framework as a prior density on the wavelet coefficients of the data, the HMT model plays the rôle of a statistical *grammar* that makes unbroken strings of L and S states preferable to broken strings. Numerous experiments with real data have verified that the HMT is an accurate and effective model for a large class of real-world signals and images [1, 2].

Unfortunately, due to the strong shift-variance of the orthogonal DWT [3], the 2Populations and (most notably) Persistence properties are strongly affected by the placement of the smooth and edgy regions in the data. In particular, the coefficient magnitudes near an edge can swing wildly as the alignment between the edge and the wavelet basis functions changes slightly (even by one sample). This weakens the assumption of Persistence, resulting in a less accurate model. To attack this problem, we need to counter the shift-variance of the wavelet transform. Traditionally, this is done by using a shift-invariant (redundant) wavelet transform [4], but HMT models in this domain can be com-

putationally burdensome.

In this paper we take an approach based on the dual tree *complex wavelet transform* (CWT) [5]. The CWT expands a signal or image in terms of a set of complex wavelets with complementary real and imaginary parts. The most important property for the present study is the near shift invariance of the CWT coefficient *magnitudes*, which leads to strong persistence of large magnitudes around edges, independent of their alignment. As an added bonus, in 2-D the CWT offers six angle-selective subbands rather than the standard DWT's three. Thus the transform is less sensitive to the angular orientation of the edges. Furthermore, the computational cost of the CWT is the same as the DWT, $O(N)$. As we will see, HMT modeling framework is easily extended to the CWT.

To demonstrate the effectiveness of the complex wavelet HMT (CHMT), we will develop a multiscale texture classification algorithm that outperforms that based on the standard DWT HMT model. Multiscale texture classification, described in Section 5, partitions an image into regions containing similar textures. More complicated segmentation algorithms use multiscale classifiers as front ends, and the segmentation quality relies on the effectiveness of the multiscale classification.

2. WAVELET HMT MODEL

For concreteness, we will emphasize images in this paper, though the ideas apply to data of any dimensionality. The 2-D orthogonal DWT consists of three subbands of coefficients [6], each of which has a quad-tree structure. Denote the *parent* of wavelet coefficient w_i as $w_{\rho(i)}$.

To statistically match the 2Populations property of the wavelet transform, we consider the collection of small/large wavelet coefficients as outcomes of a Gaussian pdf with small/large variance. This approximates the marginal pdf $f(w_i)$ of each wavelet coefficient as a *Gaussian mixture*. To each wavelet coefficient w_i , we associate a discrete hidden state s_i that takes on values $m = S, L$ with probability mass function (pmf) $p(s_i)$. Conditioned on $s_i = m$, w_i is Gaussian with mean $\mu_{i,m}$ and variance $\sigma_{i,m}^2$. Thus, its overall marginal pdf is given by¹

$$f(w_i) = \sum_{m=S,L} p(s_i = m) f(w_i | s_i = m), \quad (1)$$

with $f(w_i | s_i = m) \sim N(\mu_{i,m}, \sigma_{i,m}^2)$. While each wavelet coefficient w_i is conditionally Gaussian given its state variable s_i , overall it has a non-Gaussian density due to the randomness of s_i .

To match the Persistence property of large and small coefficients, we set up a Markov-1 dependency structure on

¹The number of states can be increased beyond two to match the marginal distribution with arbitrary precision. However, we have found that a model with two states provides a fine accuracy/complexity balance.

the hidden states across scale (a hidden Markov model) [1]. Using links to denote dependencies, the HMT model takes the form of a tree. The state transition probabilities between the connected states model the persistence of large/small coefficient magnitudes across scale. The overall HMT model consists of an HMT for each of the three DWT subbands.

The HMT model parameters consist of the Gaussian mixture means and variances $\mu_{i,m}, \sigma_{i,m}^2$, the transition probabilities $p(s_i | s_{\rho(i)})$, and the pmf $p(s_0)$ for the root state s_0 . Group these into the parameter vector Θ . In practice, we usually share the same parameters within each scale band [1]. This process, called *tying*, makes the HMT model more robust to over-fitting.

The HMT parameters can be trained to capture the wavelet-domain features of the image(s) of interest using the iterative expectation-maximization (EM) algorithm [1]. For a given set of training data, the trained model $f(\mathbf{w} | \Theta)$ approximates the joint pdf of the wavelet coefficients. See [1, 2] for more details.

3. COMPLEX WAVELET TRANSFORM

The dual tree CWT comprises two parallel wavelet filter bank trees that contain carefully designed filters of different delays that minimize the aliasing effects due to decimation [5]. Each tree produces a valid set of *real* DWT coefficients u_i and v_i ; together they form the *complex coefficients* $c_i = u_i + jv_i$.² The CWT is near shift invariant and, in 2-D, provides good directional selectivity with six oriented subbands per scale [5].

In 2-D, the CWT basis functions closely approximate modulated complex exponentials (Gabor functions) of the form

$$h(x, y) = a(x, y) e^{j(\omega_x x + \omega_y y)} \quad (2)$$

with $a(x, y)$ a slowly varying Gaussian-like real window function centered on $(0, 0)$, and (ω_x, ω_y) the center frequency of the corresponding subband. The real and imaginary parts of the CWT basis functions are symmetric and antisymmetric respectively about $(0, 0)$ and are therefore orthogonal. This means that the real and imaginary parts of each CWT coefficient are approximately statistically uncorrelated.

Furthermore, since $a(x, y)$ is slowly varying, the *magnitude* $|c_i| = \sqrt{u_i^2 + v_i^2}$ of each CWT coefficient is insensitive to small image shifts. It therefore forms a more accurate estimate of image activity at a given location and scale than the corresponding coefficient of a real DWT, which suffers from shift variance.

The directional properties of the CWT arise from the fact that $h(x, y)$ has constant phase along lines such that $\omega_x x + \omega_y y$ is constant, giving filters selective to edges parallel to this direction. For the six subbands at each scale,

²Alternatively, the CWT can be interpreted as a special wavelet tight frame with a redundancy factor of two [6].

$\omega_y/\omega_x \approx \{-3, -1, -\frac{1}{3}, \frac{1}{3}, 1, 3\}$, which produces bands oriented at approximately all odd multiples of 15° .

4. COMPLEX WAVELET HMTs

Due to its near shift invariance, the progressions of large and small magnitudes in the CWT coefficients c are more reliable than in either the real part u or imaginary part v alone. In this section, we will leverage this reliability into a robust HMT model for the CWT.

In the simplest method, we associate with each CWT coefficient c_i a single hidden state q_i taking value S, L depending on whether $|c_i|$ is small or large. Consider each complex coefficient c_i as a 2-D random vector (u_i, v_i) , and recall that since the real and imaginary filter banks are orthogonal, the real and imaginary parts are approximately uncorrelated random variables. Thus we approximate the marginal density $f(c_i)$ as a two-state, 2-D Gaussian mixture

$$f(c_i|q_i = m) := \frac{1}{2\pi\sigma_{i,m}^2} \exp\left(-\frac{u_i^2 + v_i^2}{2\sigma_{i,m}^2}\right). \quad (3)$$

Factoring (3) into

$$f(c_i|q_i = m) = \frac{1}{2\pi\sigma_{i,m}^2} e^{-u_i^2/2\sigma_{i,m}^2} e^{-v_i^2/2\sigma_{i,m}^2} \quad (4)$$

reveals that we model the real and imaginary parts as two-state, 1-D Gaussian mixtures with *shared state variable* q_i . This is quite reasonable: Small $|c_i|$ result only when both $|u_i|$ and $|v_i|$ are small simultaneously (smooth region). This is captured by $q_i = S$. On the contrary, large $|c_i|$ result when either $|u_i|$ is large, $|v_i|$ is large, or both are large (edge region). This is captured by $q_i = L$. (Note that, as in the DWT HMT case, small outcomes from the L-state Gaussian mixture density are entirely possible – and in fact likely – since this component has zero mean.)

This approach is equivalent to modeling each $|c_i|$ as a two-state Rayleigh mixture model. The formulation (3)–(4) (coupled Gaussian mixtures for the real and imaginary parts) is preferable, however, as direct Rayleigh modeling leads to unmanageable posterior distribution expressions.

The CWT HMT (CHMT) corresponding to (3) with scale-to-scale Markov transitions has a structure identical to the real DWT HMT of Section 2 and [1]. The only differences are the substitution of (3) for (1) and the use of six subband trees instead of three. The result is an HMT that supports $O(N)$ coefficient, computation, training and inference algorithms and features better angle selectivity.

A denoising algorithms based on the CHMT, presented in [7], is a testament to the prowess of the CHMT model. It typically offers a 1dB gain over standard techniques based on real-valued wavelets (including redundant techniques).

As an alternative to the above, we could model the u and v DWTs separately using standard 2-state, 1-D HMTs.

The result is a 4-state, 2-D HMT for each $|c_i|$ that depends on the four combinations of large/small u_i and v_i . Tying the u and v HMTs node by node by forcing them to share the same mixture means and variances (but not hidden state values) effectively models u and v as independent realizations of the same random process. Thus, we can apply the training and inference algorithms for multiple data observations described in [1]. We will not pursue this approach here, however.

5. APPLICATION: MULTISCALE CLASSIFICATION

With a wavelet-domain HMT model in hand, many statistical image processing tasks, such as estimation, classification, and segmentation, are straightforward [1, 2]. In this section, we will use the CHMT to model the hypotheses (textures) in a multiscale maximum likelihood classification algorithm.

Consider the standard *texture classification problem*: given probability models $f(x|H_i)$ for a set of textures $\{H_i\}$ and a data set x of size n , we must decide which of the texture models best describes x . This decision is based on the texture model that yields the highest likelihood, i.e., we choose the H_i that maximizes $f(x|H_i)$. As n grows, the decision becomes more reliable.

A more interesting problem is the *supervised segmentation problem*: given the $f(x|H_i)$ and an image comprised of a montage of homogeneous texture regions, we must affix labels to the regions in the image that correspond to each texture. The solution to this problem is less straightforward, since we have no information regarding the *shapes* of the regions. Given shape information (and a model for the texture in each shape), we can use the maximum likelihood technique described above to classify each region independently.

Multiscale classification acts as a bridge between these two problems [2]. At scales $j = 0, 1, \dots$, we divide the $N \times N$ image into dyadic squares with side length $\frac{N}{2^j} \times \frac{N}{2^j}$ and then classify each dyadic square using the maximum likelihood technique. The result is a set of “raw segmentations” of the image, where we have assumed that the shapes of the texture regions are dyadic squares. The raw segmentations at coarse scales (small values of j) are based on many data points, and hence the decisions are more reliable than those at fine scales (large j). However, the raw segmentations at fine scales have better resolution; the smaller dyadic squares more accurately approximate the true shapes of the texture regions. Given set of raw segmentations, we can develop a fusion algorithm [2, 8] that combines them into a final segmentation.

Wavelet based texture models, such as the CHMT, are ideally suited to the multiscale classification problem. A subtree of wavelet coefficients, with its root at a scale j , contains information about the image inside a dyadic square

of side length $N2^{-j}$. By examining all wavelet subtrees of an image, we can assign a label to each dyadic square depending on which texture the subtree of wavelet coefficients best describes [2].

Wavelet HMT based methods break the solution into two steps [2]:

1. Train HMT models for each texture. This requires samples (and hence a priori knowledge) of the textures in the image.
2. Compute the likelihood of the image wavelet coefficients under each model at multiple scales, and assign the label corresponding to the model that maximizes the likelihood.

HMT-based multiscale classification results using real and complex wavelets are shown in Fig. 1. The algorithm based on complex wavelets outperforms (gives fewer errors than) that based on real wavelets, which leads us to believe that complex wavelets capture more of the textures' key structures.

We can use the multiscale classification as a front end to a supervised segmentation algorithm [2]. Segmentation algorithms use a priori information regarding the shape of the texture regions to combine the raw segmentations into a final segmentation map. For example, [2] presents an algorithm based on a context model for shape, while [8] uses one based on description length. The CHMT multiscale classifier can be inserted into either of these algorithms without modification. Since the multiscale classification is more accurate using the CHMT, we expect that there will be improvement in the end segmentation results.

6. CONCLUSIONS

The ability of multiresolution signal and image models to capture the structures of signals and images is often hampered by the shift variance of the underlying wavelet transform. In this paper, we have shown that, using complex wavelets, we can design statistical models that focus on the salient signal features (persistence across scale of edges and so forth) rather than artifacts due to shift variance. As our simple classification example has demonstrated, the CHMT outperforms methods based on traditional wavelet transforms, due to the parsimony and better angular resolution of its underlying transform.

While we have chosen to illustrate the application of the CHMT with a classification problem, this new model is generally applicable to Bayesian inference problems, including denoising [7], synthesis, compression and fusion. The near shift invariance and improved angular resolution of the CWT should benefit these applications as well.
